Keywords: MSWI FA, Alkali washing pre-treatment, Bubbles, Heavy metals

To reveal the specific reason for the bubble release and expansion of municipal solid waste incineration fly ash (MSWI FA) during polymerisation, the chemical composition and source of the emitted gas were studied at length in this paper. To further explore the advantage of an alkali washing pre-treatment for MSWI FA, the influence and mechanism of the alkali washing pre-treatment on the macroscopic mechanical properties, microscopic pore structure and heavy metal leaching of geopolymers have been investigated. The results show that the emerging bubbles are mainly H$_2$ and NH$_3$ released by the reaction of elemental aluminium and ammonium salts from MSWI FA with alkali, respectively. The alkaline washing pre-treatment can ensure the volume stability of the geopolymers by releasing bubbles in advance, which is conducive to improving the strength of hardened paste and hindering the leaching of heavy metals. Although the alkaline washing process cannot significantly remove heavy metal ions directly, it can remove almost all the soluble chlorine salts and has a certain significance for the development of the overall compressive strength.

INTRODUCTION

With the continuous growth of urban waste, waste incineration has the advantages of saving land resources, protecting the environment and generating electricity, so it has become the mainstream method of waste disposal in recent years [1]. The latest figures show that the disposal rate of municipal solid waste in China has exceeded 99.9%. Furthermore, incineration disposal and safe landfills account for 72.5 and 21.0% of the total treatment, respectively. Before the year 2022, China had 583 domestic waste incineration stations, with a daily waste incineration capacity of more than one million tonnes [2]. At the same time, generating electricity from municipal solid waste, an effective and creative waste-to-energy approach, is nowadays a widely accepted technology that helps reduce the volume by 80% and relieve any power tension [3]. As a by-product of the waste incineration power plant, municipal solid waste incineration fly ash (MSWI FA) has been labelled as hazardous waste all over the world owing to its higher content of potentially toxic heavy metals and organic pollutants [4-9]. In terms of the safe utilisation of the MSWI FA, the most concerned focus is how to ensure a lower volume expansion rate and toxic heavy metal leaching rate [10-12].

Geopolymers have attracted more and more interested scholars in recent years, largely due to saving non-renewable energy [13, 14], reducing carbon dioxide emissions [15], their excellent mechanical properties as well as having reliable durability [16-18]. At the same time, geopolymers have better toxic metal solidification/stabilisation properties than Portland cement by adsorption, physical encapsulation, chemical bonding, and so on [19-21]. These environmental benefits and unique advantages make geopolymers an ideal selection for MSWI FA. Research studies have shown that MSWI FA can realise the reuse of resources, such as mineral admixtures and precursors of geopolymers, due to the pozzolanic activity and considerable Ca and Al elements [22-24]. Al-Ghouti et al [25] showed that geopolymers prepared with MSWI FA can replace traditional cement-based materials to a certain extent. Jin [26] and Tian [27] pointed out that a small amount of MSWI FA is conducive to strength development and durability optimisation, which may be due to the introduction of active elements in MSWI FA. Lei et al. [28] successfully prepared a product with a strength of over 21 MPa at 7 d by reacting pure MSWI FA with a complex alkali solution. Zheng et al [29] and Wongsa et al. [30] prepared products with a strength of 73.57 and 53.0 MPa for 28 d using MSWI FA, respectively. MSWI FA has shown to have remarkable potential for its base-stimulating activity.

Some experimental studies have found that the pre-treatment of MSWI FA before alkali activation can particularly reduce the toxic metal leaching rate [31]. Lin et al. [32] enhanced the ability of MSWI FA...
to fix Cr by ultrasonic-assisted washing. Chen et al. [33] found that the mechanical activation of MSWI FA could improve the strength of the material and reduce the leaching of toxic metals by adjusting the amount of nitric acid and sodium carbonate. Dontriros et al. [34] removed chloride ions and sulfate ions, and effectively inhibited the leaching of toxic metals. Zheng et al. [29] explained that a water-wash can remove almost all the NaCl and KCl, improving the degree of polymerisation of the geopolymer, as well as reducing the toxic metal leaching. However, the above studies cannot solve the problem of volume expansion caused by the gas formation of MSWI FA in an alkaline environment. Although few articles have mentioned that an alkaline washing pre-treatment may prevent the occurrence of volume expansion, the cause and mechanism of the expansion are still unclear. At the same time, the pungent odour associated with the occurrence of the gas is clearly not caused by the elemental aluminium alone, and there is no relevant research on its source.

Therefore, starting from the generated gas, this paper explores the chemical composition and source of the gas. In addition, the effect of the released gas on the pore structure of the hardened slurry is explained. Combined with the removal effect of soluble chlorine salts, the advantages and mechanism of the alkaline washing pre-treatment are comprehensively explained. Finally, it is sincerely hoped that the reasonable resource utilisation of MSWI FA can be a contribution of this paper.

EXPERIMENTAL

Materials

MSWI FA

All the MSWI FA in this work was produced from mechanical grate furnaces and provided by the Waste Incineration Power Plant of China Everbright Group. It is important to note that the MSWI FA is taken directly from the bottom of the chimney and has not been treated with chelating agents. The elementary composition and particle distribution of MSWI FA can be seen in Table 1 and Figure 1a respectively.

GBFS, Steel, and Fly ash

The GBFS, steel, and fly ash are provided by Shandong Jingnuo Building Materials Co., Ltd., China, and their chemical composition and particle distribution can be seen in Table 1 and Figure 1b, c, d respectively.

$\text{Na}_2\text{SiO}_3$

The $\text{Na}_2\text{SiO}_3$ was provided by Suzhou Youchuang Chemical Environmental Protection Technology Co., Ltd, China, and its modulus is 2.4 in this work.

Methods

Alkaline washing pre-treatment

To systematically demonstrate the influence of the alkaline wash pre-treatment on the ingredients in the MSWI FA, a set of specific experimental procedures were used that can be seen in Figure 2. Prior to the experiment, 100 g of MSWI FA was put into conical bottles. By adjusting the amount of the alkaline control water, the solid ratio and pH were adjusted to 5:1 and 9, respectively. The upward exhaust air method was used to collect the gas substances generated in the experiment, and then a gas chromatography-mass spectrometer (GC–MS) was used for the gas composition analysis. The MSWI FA in the conical bottles was collected and analysed by an X-ray diffractometer (XRD), an organic composition analyser, and a Fourier transform infrared spectrometer (FT-IR).

SP analysis

Spectrophotometry (SP) was used to detect the $\text{NH}_4^+$ in the MSWI FA washing solution. To conduct the experiment, different volumes of an ammonium standard solution ($0.01 \text{mg} \cdot \text{mL}^{-1}$) were absorbed into a 50 ml colorimetric tube, namely 0, 0.5, 1.0, 3.0, 5.0, 7.0, and 10.0 mL. Then, 1 mL of potassium sodium tartrate ($\text{KNaC}_4\text{H}_4\text{O}_6 \cdot 4\text{H}_2\text{O}$) and 1.5 mL of a sodium reagent (containing NaOH, KI, and HgI$_2$) were added to the tube, followed by dilution with water up to the marked line. Using a wavelength of 430 nm and a path length of 10 mm, the absorbance of each solution was measured, and a standard curve was plotted. Likewise, drops of the MSWI FA washing liquid were
added to a 50 ml colorimetric tube, along with 1 mL of potassium sodium tartrate and 1.5 mL of the sodium reagent. The absorbance of these samples was measured, and the NH$_4^+$ content was determined by comparing it with the values obtained from the standard curve.

**XRD analysis**

The XRD patterns were obtained with an X-ray diffractometer (D8-Advance) made by Bruker in Germany. With this instrument, the consistent test rate was set to 4 °·min$^{-1}$, ranging between 10° and 90°, in steps of 0.05°.

**XRF and ICP-MS analysis**

The XRF and ICP-MS were obtained using an X-ray fluorescence spectrometer (S2 PUMA Series II) and an Inductive Coupled Plasma Emission Spectrometer (Elan DRC-e, PerkinElmer), respectively.

**FT-IR analysis**

An FT-IR analyser (Thermo Fisher, Nicolet iS5, USA) was used for the raw MSWI FA and pre-treated MSWI FA. In this experiment, the test range of the sample was from 400 to 4000 cm$^{-1}$.

**Preparation and curing of the samples**

All the raw materials are made from the same batch and were processed in a room at 20 ± 2 °C. A Na$_2$SiO$_3$ powder was used for the alkali-active substance, with the water-binder ratio being controlled to 0.45. The specific experimental mix can be seen in Table 2. Among the mixes, the MSWI FA used in FA-2, 4, 6, and 8 were pre-treated by alkali washing. Six samples with dimensions of 40 × 40 × 160 mm were prepared with each ratio and placed in a standard curing box (25 ± 2 °C, greater than 95 % humidity) until the next test was performed.
The uniaxial unconfined compressive strength of the geopolymer was collected by a universal testing machine (MTS, CMT5504, 100 KN). All the geopolymer samples were placed on the test bench in turn, with a loading speed of 5N\(\cdot\)s\(^{-1}\) selected. Six samples of each group were measured and their average value was taken as the final result.

Pore structure analysis

The pore structure analysis was performed by a low field NMR instrument (MacroMR12-150V-I). For the measuring accuracy of the results, the sample should be strictly maintained at 25 °C all the while. With the sampling frequency set to 250 kHz, 4000 echoes were recorded and the time of each echo was 0.4 ms.

Heavy metal analysis

The collection process of heavy metal ions was performed through the strong acid digestion method and the HJT300-2007 standard leaching test, respectively. The detection process was determined by inductively coupled plasma optical emission spectrometry (ICP-OES; Prodigy XP, Leeman-Labs).

RESULTS AND DISCUSSION

Results of the alkaline washing pre-treatment

Gas phase analysis

In the process of preparing the hardened paste by MSWI FA and the alkali solution, a large number of bubbles will be produced, resulting in the volume expansion of the paste and accompanying pungent odour. To collect as pure a sample as possible, the gas collection time is limited to the first two hours with the fastest generation rate [35]. The gases collected from the device were imported into the GC-MS for the gas composition analysis, and the analysis results are shown in Table 2. It is obvious that H\(_2\) is the main product of all the formed gases, with a content of 85.7 %. Considering the chemical composition of the MSWI FA, only the elemental aluminium can react with the alkali solution to produce H\(_2\). The elemental aluminium remains protected by a thin film of alumina, which explains the source of the H\(_2\), and the reaction equation that is shown in (1).

\[2\text{Al} + 20\text{OH}^- + 2\text{H}_2\text{O} \rightarrow 2\text{AlO}_2^- + 3\text{H}_2 \]  \hspace{1cm} (1)

\[\text{NH}_4^+ + \text{OH}^- \rightarrow \text{NH}_3 + \text{H}_2\text{O} \]  \hspace{1cm} (2)

H\(_2\) can also explain the MSWI FA expansion reaction with the alkali solution, but still cannot explain the pungent odour source. Therefore, it is reasonable to assume that there may be another gas that has not been detected because the concentration is too low to meet the detection limit of the GC-MS. The sample (before and after the alkali wash pre-treatment) is completely burned in the oxidation tube at 1150 °C in a pure oxygen atmosphere to produce CO\(_2\), H\(_2\)O, NO\(_x\), SO\(_2\), SO\(_3\) and other gases, and then the mixture is further reduced into CO\(_2\), H\(_2\)O, N\(_2\), SO\(_2\) and other gases in the reduction tube (850 °C, reduced copper). After separation by the adsorption-desorption column, the thermal conductivity detection after separation was carried out through a chromatographic column. The contents of the C, H, N and S elements were obtained, and the results are shown in Table 3. This result shows that the alkaline washing pre-treatment reduced the N and S elements in the MSWI FA by 1.23 and 0.54 %, respectively. NH\(_3\), SO\(_2\) and SO\(_3\) all give off pungent odours. NH\(_3\) is the product of the reaction of the alkali solution with the ammonium salt in MSWI FA, as in Equation (2), while SO\(_2\) and SO\(_3\) are derived from the attachments during the high-temperature formation of MSWI FA.

To further prove the existence of the ammonium salt in MSWI FA, NH\(_4^+\) was detected by a spectrophotometer. Figure 3 shows the determination results. The standard
The absorbance measured by the 50 mL MSWI FA washing solution (water solid ratio is 5:1) with the standard curve, the mass of NH$_4^+$ can be obtained, and then the concentration of the ammonium salt in the washing solution can be calculated as 1.2 ppm. The presence of NH$_4^+$ in the washing solution provides the possibility for the formation of NH$_3$ during the alkaline washing process. On the other hand, the NH$_3$ detection tube (Figure 4) was used to measure 23 mg·m$^{-3}$ in the sample gas through the principle of the linear colorimetric method, which further confirmed that NH$_3$ could be released by the reaction of MSWI FA with the alkali solution.

XRD analysis

The collected XRD information of MSWI FA is shown in Figure 5. Chlorine salts (NaCl, KCl, and CaClO$_4$) and calcium salts (CaCO$_3$, CaSO$_4$, and Ca(Al, Si)$_2$O$_4$) are the dominant state of existence in MSWI FA [36], which corresponds to the results of the previous elemental analysis. Specifically, the chlorine elements mostly existed in the forms of soluble chloride such as NaCl, KCl, and CaClO$_4$, and their content decreased significantly after the alkaline washing pre-treatment. It is worth noting that calcium salts contribute to the formation of products and the improvement of the properties in the cementitious material system. Whether MSWI FA is used for solidified landfills or recycled resources, calcium salts can play a certain contribution [37]. The decrease in the chlorine content leads to an increase in the calcium content, so MSWI FA can play a better role in the cementitious material system after the alkali washing pre-treatment, which is consistent with the previous conclusions [38].

XRF and ICP-MS analysis

Comparing the elemental changes in the raw and the washed MSWI FA, it can be observed that the percentage content of the Cl significantly decreases,
while the content of K and Na also decreases to varying degrees. On the other hand, the content of the other elements, such as Ca, Si, and Al, increases. This can be attributed to the alkali washing pre-treatment process, which effectively removes a large portion of chloride salts and results in the enrichment of Ca, as shown in Table 4. However, the alkaline washing process is not effective in removing heavy metal ions other than Pb, as shown in Table 5, which may be due to the high solubility of Pb in water.

**FT-IR analysis**

The FTIR analysis is helpful for an in-depth analysis of the molecular structure and chemical bonds between the atoms of the MSWI FA. Figure 6 shows the chemical state of the MSWI FA (raw or washed), which is mainly composed of six absorption peaks. The narrow absorption peak at 875 cm\(^{-1}\) corresponds to the symmetrical stretching vibration of O-C-O [39], which corresponds to the presence of CaCO\(_3\) in Figure 4. The peak at 970 cm\(^{-1}\) is represented by the tensile vibration of the Si-O-Si bond in the silicate [40], corresponding to the Ca(Al,Si)\(_2\)O\(_4\) mineral in the XRD analysis. The wide absorption peak at 1124 cm\(^{-1}\) is related to the asymmetric stretching vibration of S-O [41], which is related to the presence of SO\(_4^{2-}\). The absorption band of 1437 cm\(^{-1}\) is related to the asymmetric stretching motion of the O-C-O bond in the CO\(_3^{2-}\) [42]. The absorption peak at 1637 cm\(^{-1}\) is related to the bending vibration of the H\(_2\)O-H in the bound water. Finally, the wide absorption peak at 3439 cm\(^{-1}\) is attributed to the stretching vibration of the Al-OH bond in the [Al(OH)\(_6\)]\(^{3-}\) octahedral structure [43]. The washed MSWI FA has a higher peak at 3439 cm\(^{-1}\), further proving that more elemental aluminium was involved in the reaction with the alkali solution, as shown in Equation (1) and (3).

\[
AlO_2^- + 2OH^- + 2H_2O \rightarrow [Al(OH)\(_6\)]^{3-}
\]  

(3)

**Compressive strength analysis**

To investigate the improvement effect of the alkaline washing pre-treatment on the macroscopic performance of the MSWI FA, the washed MSWI FA was tested for its compressive strength. Different mix ratios were designed with MSWI FA, GBFS, steel slag, and fly ash, as illustrated in Table 6.

Table 6. The mix ratio of the experimental samples (g).

Note: The MSWI FA used in FA-2, FA-4, FA-6 and FA-8 is washed with alkali

The compressive strength of the samples with the different proportions and different curing ages is shown in Figure 7. FA-1 and FA-2 are the samples prepared from pure MSWI FA, and FA-2 obviously has higher strength than FA-in each age after the alkaline washing pre-treatment, which indicates that the removal
of the gas and soluble chlorine salts by alkaline washing pre-treatment is very beneficial to the development of the strength. It is the pure MSWI FA prepared samples that have relatively lower strength, whose strength at 1 and 28 d do not exceed 0.5 and 3 MPa, respectively. FA-3 and FA-4 have significantly higher strength, and the strength at 28 d can reach more than 16 MPa, which shows that MSWI FA still has some value to partially replace the cementitious material and can be reused as a resource. The combination of MSWI FA and steel slag (FA-5 and FA-6) has no outstanding performance, whose strength at 1 and 28 d is less than 1 and 5 MPa, respectively, because the MSWI FA and steel slag are rich in Ca elements, but lack Si and Al elements that provide any skeletal support in the cementing system [44]. The strength of FA-7 and FA-8 at 28 d can reach about 10 MPa, which is closely related to the action of the fly ash. Although the strength difference between the different proportions was obvious, the alkaline washing pre-treatment under the same proportion of each group is always beneficial to improve the strength. This is due to the fact that alkaline washing pre-treatment can remove, in advance, the ammonium salts and elemental aluminium that produce the expansive gases as well as soluble chlorine salts that are not beneficial to the strength development.

**Pore structure analysis**

The low-frequency NMR can describe the pore structure of the sample qualitatively, as shown in Figure 8. Two obvious peaks can be found in each sample, where the higher and lower peaks represent the distribution of small holes from 1 to 100 nm, and the distribution of holes from 100 to 10000 nm in the sample, respectively. It can be seen that the number of small wells of the sample under the same ratio after the alkaline washing treatment decreases sharply, and the number of large wells also decreases overall. Undoubtedly, the pore structure of the sample made by the pure MSWI FA changed most obviously after the alkaline washing pre-treatment.

For the further quantitative description and in-depth exploration of the pore structure, it is necessary...
Benefits of alkaline washing pre-treatment of MSWI FA before alkali-activation

Ceramics – Silikáty 68 (3) XX-XX (2024)

Figure 8. Pore distribution of the different samples.

Figure 9. Comparison of the classification porosity under the different experimental proportions.

to classify the pore types according to the degree of damage to the structure. Specifically, that is the porosity range corresponding to the sample from 0 to 20 nm, 20 – 50 nm, 50 – 200 nm, and above 2000 nm are considered harmless pores, less harmful pores, harmful pores, and multi-hazard pores [45]. Figure 9 shows the comparison of the classification porosity under different experimental proportions. Not only the change in the total porosity under each ratio is clear at a glance (FA-1→FA-2: 12.35→7.83; FA-3→FA-4: 11.77→9.75; FA-5→FA-6: 11.35→10.36; FA-7→FA-8: 11.64→9.78), but also the change in the number of various types of pores is very obvious.

It is not difficult to see that the number of multi-hazard pores and harmful pores has decreased significantly, and the number of harmless pores has decreased slightly, while the number of harmless pores has not changed significantly. It can be inferred that the bubbles of the elemental aluminium and ammonium salts in the MSWI FA react with the alkali solution are mostly multi-hazard pores and harmful pores, which also explains the main reason for the increase in the strength under the same ratio after the alkali washing pre-treatment from the perspective of the micro-structure.
Heavy metal analysis

Figure 10 and Figure 11 show the total concentration and leaching concentration of the heavy metals under the different experimental ratios in Table 4, respectively. It can be clearly seen from Figure 10 that the concentration of various heavy metals is positively correlated with the amount of MSWI FA in the mix ratio. Almost all the samples have a high concentration of these targeted metals, and their total concentration follows the order of Zn > Pb > Ba > Cu >> Mn > Cd > Cr > Ni. The reason why the concentration of heavy metals represented by Zn do not decrease, but increased slightly after the alkaline washing pre-treatment with the same proportion is that the alkaline washing process takes away a large amount of soluble chlorine salts and indirectly increased the total concentration of the heavy metals, which is consistent with the conclusion of the XRD analysis.

As shown in Figure 11, with the exception of the heavy metal Zn, only a few other heavy metals are leached. Cd and Ni are almost non-leached, which is because they are inherently less abundant than the other heavy metals. After the alkaline washing pre-treatment, the leaching concentration of all the heavy metal ions decreased overall. This phenomenon can be explained by the pore structure (Wang et al., 2022). In the process of alkali washing, a large amount of gas is released in advance to ensure the structure density of the hardened slurry and inhibit the leakage of the heavy metal ions. It is further proved that the alkaline washing pre-treatment can reduce the leaching of heavy metals. From the point of view of heavy metals, the alkali washing pre-treatment is beneficial to MSWI FA, no matter the landfill treatment or resource utilisation.

CONCLUSIONS

This paper mainly studied the optimisation of alkaline washing MSWI FA for the preparation of geopolymers. According to the test results, the following conclusions have been established:

1. The inherent elemental aluminium and ammonium salt in the MSWI FA are the main factors affecting the gas formation and volume instability. The elemental aluminium and ammonium salt will produce H₂ and NH₃, respectively, in an alkaline environment, resulting in the constant expansion of the slurry in the hardening process and destruction of the structural stability.

2. The alkaline washing pre-treatment can release the gas produced in the MSWI FA in advance, ensure the structural stability of the hardened slurry, and help to prevent the leaching process of heavy metals.

3. The alkaline washing pre-treatment can also wash away the soluble chlorine salts which do not contribute to the reactivity, which is beneficial to improve the mechanical properties of the geopolymers prepared by the MSWI FA.

4. Although the alkaline washing pre-treatment will not reduce the total concentration of the heavy metals in the MSWI FA, it can prevent the leaching behaviour of the heavy metals by improving the pore structure. Therefore, the alkaline washing pre-treatment process is beneficial for both the safe landfill and the recycling of MSWI FA.
